In Entity A I have an attribute column which updates this attribute in Entity B. I can do that fine, but the problem I'm running into is that Entity B has a large set of fields, and it takes a while to do all the updates. Right now, because of the large number of records in Entity B, I'm performing the update in small chunks of about 1,000 records at a time, and doing Entity A/B updates in a threaded manner. This works ok for my specific set of tests, but doesn't really feel correct in the long-term. Is there any better way to handle this? A: As noted in the comments, doing this in a thread isn't a bad approach. However, it will be poorly scaled if the number of users grows. If you are serving 100K+ records over and over, you are using 100K+ threads to do them. All those threads will have to contend for CPU and memory. However, if you run into scaling problems with this solution, you can always consider using a background process or a service to do the inserts/updates. Sixty-nine percent of respondents

Such flat panel displays typically have a display screen or faceplate, and a light source or backlight. The faceplate includes a TFT array substrate on which pixels are defined. The TFT array substrate is typically transparent so that light from the backlight can pass through to the faceplate to illuminate the pixels. Light emitting diodes (LEDs) are fast becoming a common light source used in displays, especially for flat panel displays such as LED arrays as direct backlight sources in LCD panels. Although display screens themselves are typically made from liquid crystal and the like, there are also very thin devices using organic light emitting diodes (OLED), plasma display panel (PDP), and organic light emitting diode (OLED) technology for displays. Some displays use one or more LED light sources as direct backlights. A typical LED backlight will include an array of row or column lines of LED elements or pixel nodes. Each pixel node in a given column or row will typically have a row select line and a column select line, and may have other control signals in addition to the select lines. This pattern of select lines allows each pixel node in the display to be individually controlled to display the desired image. The control signals may include data control signals, such as those provided by display controller ICs, and enable control signals, such as those provided by sequential controller ICs. One concern with conventional displays, and particularly LED backlit flat panel displays, is that when the backlight is energized to generate light, there is a sharp increase in brightness of the pixels in the display that may be noticeable to the viewer. This increase in brightness is a function of the amount of light, the duty cycle and the duration of energization of the

pixels. The combination of the display brightness and the smaller feature size of the pixels in a flat panel display can lead to the so-called "pixel crosstalk" problem. In short, when an observer views the display, the observer will perceive the image as an alternating sequence of bright and dark squares or squares arranged in rows and columns. The observer will typically see this as an area
